

EE5203 L02 Lab Guide

Process eight sensor values with decisions and loops - Basri Erdogan

Mission: Copy your working L01 project and process eight simulated sensor values in one `main.c` file. Clamp invalid values, calculate an average, count high values, and select a numeric status. Prove every result in the debugger.

Prepare before class

- ☐ Bring your working L01 Nucleo-F401RE project and USB data cable.
- ☐ Review assignment, arithmetic, `if/else`, `for`, and array indices.
- ☐ Complete the entry ticket below.

```
int x = 3;
x = x + 2;
x++;
```

1. What is the final value of `x`?
2. Which symbol compares two values: `=` or `==`?
3. What are the valid indices of `int values[4]`?

Learning objectives

By checkoff time, you can:

1. trace assignments and arithmetic statements in order;
2. use comparisons in `if/else` decisions;
3. trace a `for` loop from its first to last valid counter value;
4. process every element of an eight-element array;
5. use debugger evidence to justify a prediction.

Hardware and files

Item	Required value
Board	Nucleo-F401RE
Tools	STM32CubeMX + VS Code
Starting point	Working copy of the L01 project
Project name	EE5203_L02_<studentnumber>
File you edit	Generated <code>Core/Src/main.c</code>
New source/header files	None
Input	Eight fixed <code>uint16_t</code> values
Evidence	Build console, breakpoint, Watch/Expressions

Keep all edits to generated `main.c` inside the appropriate USER CODE regions.

Rules

The eight fixed input values are declared in Checkpoint B. Rules:

- valid sensor values are 0 through 4095;
- a value above 4095 must become 4095;
- a high sample is strictly greater than 2500;
- status code is -1 below 1500, 1 above 3000, otherwise 0.

Warm-up (first 15 minutes)

Before editing, trace this loop on paper:

```
int total = 0;

for (int i = 0; i < 3; i++) {
    total += i;
}
```

Write the value of `i` and `total` after every repetition, name the initialization / condition / update parts, and say why `i <= 3` would be wrong for a three-element array.

Checkpoint A - Copy and build the project

1. Copy the L01 project and rename it `EE5203_L02_<studentnumber>`.
2. Build the unchanged copy; confirm zero errors.
3. Locate USER CODE BEGIN 2 in `main.c`.

Evidence: Show the copied project name and the successful build.

Checkpoint B - Declare the data and result variables

Inside USER CODE BEGIN 2, before the generated `while (1)`, add:

```
uint16_t samples[8] = {
    850, 1250, 4095, 4200,
    2050, 900, 3100, 2800
};

int sum = 0;
int average = 0;
int high_count = 0;
int invalid_count = 0;
int status_code = 0;
```

For each declaration, be able to name the type, the starting value, and the valid array indices.

Evidence: Build with zero errors and show the declarations.

Checkpoint C - Process every array element

Add this loop after the declarations:

```
for (int i = 0; i < 8; i++) {
    if (samples[i] > 4095) {
        samples[i] = 4095;
        invalid_count++;
    }

    sum += samples[i];

    if (samples[i] > 2500) {
        high_count++;
    }
}
```

Before running, answer:

1. Which input value will be changed?
2. What will replace it?
3. Which indices will the loop visit?
4. Why is `i <= 8` invalid?

Evidence: Break inside the loop, single-step two repetitions, and show `i`, `samples[i]`, `sum`, and `high_count`.

Checkpoint D - Calculate and classify the result

After the loop, add:

```
average = sum / 8;

if (average < 1500) {
    status_code = -1;
} else if (average > 3000) {
    status_code = 1;
} else {
    status_code = 0;
}
```

The numeric status is deliberate. C strings and character arrays are introduced in Lecture 3.

Before debugging, calculate the expected:

Result	Prediction
<code>samples[3]</code> after clamping	
<code>invalid_count</code>	
<code>high_count</code>	
<code>sum</code>	
<code>average</code>	
<code>status_code</code>	

Evidence: Break after the `if/else` statement and compare every observed value with the prediction.

Checkpoint E - Make one controlled change

Change only the first sample from 850 to 3500. Predict which results change and which do not, debug again, and explain any wrong prediction. Restore the original value afterwards.

Evidence: Show the revised prediction and the debugger result.

Common problems

Symptom	First check
Unknown type at build	<code>#include <stdint.h></code> is present
Result too large / loop never stops	<code>sum</code> starts at zero; <code>i++</code> is present
Memory changes unexpectedly	condition is <code>i < 8</code> , not <code>i <= 8</code>
Change has no effect	rebuild and restart the debug session

Acceptance checklist

- ☐ Project builds with zero errors.
- ☐ Only `main.c` was edited.
- ☐ Array indices stay between 0 and 7.
- ☐ 4200 is replaced by 4095.
- ☐ Sum, average, counts, and status match the prediction.
- ☐ The controlled input change is demonstrated.
- ☐ Every submitted screenshot shows readable variables.

Individual oral check

Be prepared to answer one question and make one live change:

- What is the difference between `=` and `==`?
- Why does the loop use `i < 8`?
- What value does `samples[i]` select during a repetition?
- Why must `sum` start at zero?
- Change one threshold and predict the result before running.

Submit

Submit `main.c`, the completed prediction table, one build-console screenshot, one debugger screenshot of the final array and results, and three sentences explaining the controlled change.
